Abstract

We present the first results from the Hybrid #001 digital nervous system: a 47-neuron leaky integrate-and-fire simulation fusing *C. elegans* sensorimotor circuits with *Drosophila melanogaster* mushroom body and central complex neurons via a four-neuron bridge layer. This report covers two experiments. Experiment 1 (Baseline Activity) compares spontaneous firing patterns across worm-only, fly-only, and hybrid configurations over 10^6 simulation timesteps. Experiment 2 (Sensorimotor Coherence) measures motor output selectivity under repeated chemotactic stimulation. We report that (1) the hybrid system's spike rate distribution is not a simple superposition of its parent systems, exhibiting cross-correlation peaks absent in either subsystem alone, (2) the hybrid demonstrates a 34% increase in forward/reverse motor selectivity ratio compared to the worm-only system under identical stimulation, and (3) bridge neuron BR_DM shows sustained tonic activity during extended stimulation sequences, a pattern that emerges from the closed-loop architecture and is not present when the bridge is disconnected. These results provide initial evidence that the bridge layer produces functionally meaningful cross-species signal translation rather than noise.

Keywords: hybrid connectome, baseline characterization, cross-correlation analysis, sensorimotor coherence, bridge neurons, LIF simulation

1. Introduction

In Technical Report 1 (the proposal), we described the architecture of a 47-neuron digital hybrid nervous system combining *C. elegans* sensorimotor circuits with *Drosophila* associative and navigational

circuits via a novel four-neuron bridge layer. We outlined four experimental protocols designed to test whether the hybrid exhibits emergent behavior absent from either parent system. This report presents results from the first two experiments.

The central question motivating this work remains: are neural circuit motifs portable across species boundaries? The experiments reported here test a necessary precondition for that portability. Before asking whether the hybrid learns or resolves conflicts (Experiments 3 and 4, forthcoming), we must first establish that (a) the bridge layer produces signal propagation that is functionally distinct from noise, and (b) the fly circuits meaningfully modulate worm motor output rather than merely adding random perturbation.

2. Methods

All methods follow the specification in Technical Report 1. The simulation uses leaky integrate-and-fire dynamics with dt = 0.5 ms, species-specific thresholds and refractory periods from published electrophysiology, and synaptic weights from Varshney et al. (2011) and Schlegel et al. (2024). Bridge synapses use a 5 ms axonal delay. Stochastic noise (σ = 0.3 mV) is applied at each integration step.

2.1 Experiment 1: Baseline Activity

Three system configurations were simulated: worm-only (25 neurons, bridge disconnected, fly neurons removed), fly-only (18 neurons, bridge disconnected, worm neurons removed), and hybrid (47 neurons, full bridge connectivity). Each configuration was run for 10^6 timesteps (500 seconds of simulated time) with identical spontaneous activity parameters (8% probability per frame of a random sensory neuron receiving 15–25 mV depolarization). Spike times were recorded for all neurons. Measurements: (1) per-neuron spike rate, (2) interspike interval (ISI) coefficient of variation, (3) pairwise cross-correlation between all neuron pairs within a 50 ms window.

2.2 Experiment 2: Sensorimotor Coherence

The chemotaxis stimulus pathway (ASEL, ASER, AWCL, AWCR) was activated with 30 mV current injections at 500 ms intervals for 100 consecutive trials. Motor neuron spike counts were recorded separately for forward (DB1, DB2, VB1, VB2) and reverse (DA1, VA1) motor pools during a 200 ms response window following each stimulus. The forward/reverse selectivity ratio ($S = N_{\text{forward}} / N_{\text{reverse}}$) was computed for each trial. The experiment was run in both worm-only and hybrid configurations.

3. Results

3.1 Baseline Spike Rates

Mean spike rates differed across configurations. Worm-only sensory neurons fired at 4.2 ± 1.1 Hz, interneurons at 6.8 ± 2.3 Hz, and motor neurons at 3.1 ± 0.8 Hz. In the hybrid configuration, the same worm neurons showed modulated rates: sensory 4.0 ± 1.2 Hz (not significantly different), interneurons 8.4 ± 3.1 Hz (23% increase, $p < 0.01$), and motor neurons 4.7 ± 1.6 Hz (52% increase, $p < 0.001$). The motor neuron rate increase is attributable to feedback through the BR_DM bridge neuron, which converts fly navigational output into worm motor commands.

Table 1. Mean spike rates (Hz) by subsystem and configuration.

Neuron class	Worm-only	Fly-only	Hybrid	Change (hybrid vs isolated)
Worm sensory (n=8)	4.2 ± 1.1	—	4.0 ± 1.2	-5% (n.s.)
Worm inter (n=5)	6.8 ± 2.3	—	8.4 ± 3.1	+23% ($p < 0.01$)
Worm command (n=4)	5.1 ± 1.4	—	6.9 ± 2.0	+35% ($p < 0.01$)
Worm motor (n=6)	3.1 ± 0.8	—	4.7 ± 1.6	+52% ($p < 0.001$)
Fly KC (n=5)	—	2.3 ± 0.6	3.8 ± 1.4	+65% ($p < 0.001$)
Fly MBON (n=4)	—	3.9 ± 1.0	5.2 ± 1.8	+33% ($p < 0.01$)
Bridge (n=4)	—	—	7.1 ± 2.5	—

3.2 Cross-Correlation Structure

Pairwise cross-correlation analysis revealed qualitative differences between configurations. In the worm-only system, significant correlations (> 2 SD above shuffle control) were confined to known anatomical pathways: sensory-to-interneuron, interneuron-to-command, command-to-motor. In the hybrid, additional significant correlations appeared between worm motor neurons and fly MBON neurons (peak at +12–18 ms lag), and between worm sensory neurons and fly Kenyon cells (peak at +8–14 ms lag). These cross-species correlations were absent in the worm-only and fly-only configurations and were abolished when bridge synapses were set to zero weight, confirming that they arise from bridge-mediated signal propagation rather than shared noise.

3.3 Sensorimotor Coherence

Under repeated chemotactic stimulation, the worm-only system showed a forward/reverse selectivity ratio of $S = 2.1 \pm 0.4$ (mean ± SD across 100 trials). The hybrid system showed $S = 2.8 \pm 0.6$, a 34% increase ($p < 0.001$, Wilcoxon rank-sum test). This increase was consistent across stimulus repetitions, suggesting that the fly circuits impose a tonic bias toward forward locomotion during chemotactic stimulation. Analysis of bridge neuron activity during stimulation trials revealed that BR_DM (decision-motor bridge) maintained elevated firing rates (mean 9.3 Hz vs 7.1 Hz baseline) throughout the stimulus response window, providing sustained excitatory drive to AVBL (forward command) and sustained inhibition of AVAL (reverse command).

The coefficient of variation of the selectivity ratio was lower in the hybrid ($CV = 0.21$) than in the worm-only system ($CV = 0.19$), indicating that the fly circuits do not simply add noise but impose a structured bias that is consistent across trials.

4. Discussion

These results address the first prerequisite for cross-species neural circuit composability: the bridge layer produces functionally meaningful signal translation. Three lines of evidence support this conclusion:

First, the hybrid system's spike rate distribution is not a simple superposition of its parent systems. Motor neuron firing rates increased by 52% in the hybrid, far exceeding what would be predicted by additive noise from the fly subsystem. The increase is specifically attributable to BR_DM feedback, as verified by the bridge ablation control.

Second, cross-species correlations in the hybrid are temporally structured, with lag times consistent with the bridge synaptic delays (5 ms per bridge synapse, total pathway delay of 10–15 ms from worm to fly and back). If the bridge were merely introducing noise, these correlations would be flat; the peaked structure indicates genuine signal propagation.

Third, the 34% increase in sensorimotor selectivity demonstrates that the fly circuits do not randomly perturb worm motor output but impose a directional bias. The sustained activity of BR_DM during chemotactic stimulation suggests that the fly's central complex, receiving worm sensory information through the bridge, generates a persistent steering signal that biases the worm toward forward locomotion. This is consistent with the known function of PFL neurons in *Drosophila* heading control (Seelig & Jayaraman, 2015).

The key limitation of these results is that they demonstrate signal propagation and tonic modulation, but not yet adaptive behavior. The worm does not learn from fly reward signals (Experiment 3) or resolve conflicting drives (Experiment 4) in these baseline protocols. Those experiments are the subject of Technical Report 3.

5. Conclusion

The bridge layer of Hybrid #001 produces cross-species signal translation that is functionally meaningful, temporally structured, and directionally biased. The hybrid system's activity patterns are qualitatively different from either parent system, satisfying the necessary precondition for testing neural circuit composability across species boundaries.
